

Construction of an NFA from a Regular Expression

Algorithm. (Thompson's construction)

Input. A regular expression r over an alphabet Σ .

Output. An NFA N accepting L_r .

1. For ϵ , construct the NFA

2. For a in Σ , construct the NFA

3. Suppose N_s and N_t are NFA's for regular expression s and t .

a) For the regular expression $s | t$, construct the following composite

NFA $N_{s|t}$:

b) For the regular expression st , construct the following composite NFA

N_{st} :

c) For the regular expression s^* , construct the following composite NFA

N_{s^*} :

d) For the parenthesized regular expression (s) , use N_s itself as the NFA.

Example

Let us construct NFA from the regular expression $(a | b)^*abb$

Conversion of an NFA into a DFA

Algorithm. Constructing a DFA from an NFA.

Input. An NFA N .

Output. A DFA D accepting the same language.

Initially, \mathcal{E} -closure($\{s_0\}$) is the only state in $Dstates$ and it is unmarked;

while there is an unmarked state T in $Dstates$ **do begin**

mark T ;

for each input symbol a **do begin**

$U := \mathcal{E}$ -closure(move(T, a));

if U is **not in** $Dstates$ **then**

add U as an unmarked state **to** $Dstates$

$Dtran[T, a] := U$

end

end

A state of DFA ($Dstates$) is a final state if it contains at least one final state of NFA.

Note! $move(T, a)$ is a set of NFA states to which there is a transition on input symbol a from some NFA state s in T . $Dtran[T, a] := U$ is a transition of DFA on input symbol a from state T to U .

Computation of ϵ -closure(T)

push all states in T **onto** stack

Initialize ϵ -closure(T) to T

while stack is **not** empty **do begin**

pop t, the top element, off of stack

for each state u with an edge from t to u labeled ϵ **do**

if u is **not** in ϵ -closure(T) **do begin**

add u to ϵ -closure(T)

push u onto stack

end

end

Example , Figure below shows NFA accepting the language $aa^* | bb^*$.

Example

Figure below shows NFA accepting the language $(a|b)^*abb$.

The start state of the equivalent DFA is \mathcal{E} -closure(0), which is $A = \{0,1,2,4,7\}$, since these are exactly the states reachable from state 0 via a path in which every edge is labeled \mathcal{E} . Note that a path can have no edges, so 0 is reached from itself by such a path.

The input symbol alphabet here is $\{a, b\}$. The algorithm tells us to mark A and then to compute \mathcal{E} -closure(move(A, a)). We first compute move(A, a), the set of states of N having transitions on a from members of A . Among the states 0, 1, 2, 4 and 7, only 2 and 7 have such transitions, to 3 and 8, so

\mathcal{E} -closure(move($\{0,1,2,4,7\}$, a)) = \mathcal{E} -closure($\{3,8\}$) = $\{1, 2, 3, 4, 6, 7, 8\}$.

Let us call this set B. Thus, $D_{\text{tran}}[A, a]=B$.

Among the states in A, only 4 has a transition on b to 5, so the DFA has a transition on b from A to $C = \mathcal{E}$ -closure($\{5\}$) = $\{1, 2, 4, 5, 6, 7\}$.

Thus, $D_{\text{tran}}[A, b]=C$.

If we continue this process with the now unmarked sets B and C, we eventually reach the point where all sets that are states of the DFA are marked. This is certain since there are “only” 2^{11} different subsets of a set of eleven states, and a set, once marked, is marked forever. The five different sets of states we actually construct are:

$A = \{0, 1, 2, 4, 7\}$

$D = \{1, 2, 4, 5, 6, 7, 9\}$

$B = \{1, 2, 3, 4, 6, 7, 8\}$

$E = \{1, 2, 4, 5, 6, 7, 10\}$

$C = \{1, 2, 4, 5, 6, 7\}$

State A is the start state, and state E is the only accepting state. The complete transition table D_{tran} is shown below:

state	Input Symbol	
	a	b
>A	B	C
B	B	D
C	B	C
D	B	E
E*	B	C

Finite Automata with output

One limitation of the finite automaton as we have defined it is that output is limited to a binary signal: “accept” | “don’t accept”. Models in which the output is chosen from some other alphabet have been considered. There are two distinct approaches; the output may be associated with the state (called a Moore machine) or with the transition (called a Mealy machine). We notice that the two machine types produce the same input-output mappings.

Moore machines

A Moore machine is a six-tuple $(K, \Sigma, \Gamma, \delta, \chi, s)$, where K , Σ , δ , and s are as in the DFA. Γ is the output alphabet and χ is a mapping from K to Γ giving the output associated with each state. The output of M in response to input $a_1 a_2 \dots a_n$, $n \geq 0$, is $\chi(q_0) \chi(q_1) \dots \chi(q_n)$, where q_0, q_1, \dots, q_n is the sequence of states such that $\delta(q_{i-1}, a_i) = q_i$ for $1 \leq i \leq n$. Note that any Moore machine gives output $\chi(q_0)$ in response to input ϵ . The DFA may be viewed as a special case of a Moore machine where the output alphabet is $\{0, 1\}$ and state q is “accepting” if and only if $\chi(q) = 1$.

Example

Suppose we wish to determine the residue mod 3 for each binary string treated as a binary integer. To begin, observe that if i written in binary is followed by a 0, the resulting string has value $2*i$, and if i in binary is followed by a 1, the resulting string has value $2*i + 1$. If the remainder of $i/3$ is p , then the remainder of $2*i/3$ is $2*p \bmod 3$. If $p = 0, 1,$ or 2 , then $2*p \bmod 3$ is $0, 2,$ or 1 , respectively. Similarly, the remainder of $(2*i + 1)/3$ is $1, 0,$ or 2 , respectively.

It suffices therefore to design a Moore machine with three states, q_0 , q_1 , and q_2 , where q_j is entered if and only if the input seen so far has residue j . We define $\chi(q_j) = j$ for $j = 0, 1,$ and 2 . The following figure shows the transition diagram, where outputs label the states.

Note! We use q/a as a state indicate that $\chi(q)=a$.

On input 1010 the sequence of states entered is q_0, q_1, q_2, q_2, q_1 , giving output sequence 01221. That is, ϵ (which has “value” 0) has residue 0, 1 has residue 1, 2 (in decimal) has residue 2, 5 has residue 2, and 10 (in decimal) has residue 1.

Mealy machines

A Mealy machine is a six-tuple $(K, \Sigma, \Gamma, \delta, \chi, s)$, where all is as in the Moore machine, except that χ maps $K \times \Sigma$ to Γ . That is, $\Gamma(q, a)$ gives the output associated with the transition from state q on input a . The output of M in response to input $a_1 a_2 \dots a_n$, $n \geq 0$, is $\chi(q_0, a_1) \chi(q_1, a_2) \dots \chi(q_{n-1}, a_n)$, where q_0, q_1, \dots, q_n is the sequence of states such that $\delta(q_{i-1}, a_i) = q_i$ for $1 \leq i \leq n$. Note that this sequence has length n rather than length $n + 1$ as for Moore machine, and on input ϵ a Mealy machine gives output ϵ .

Example,

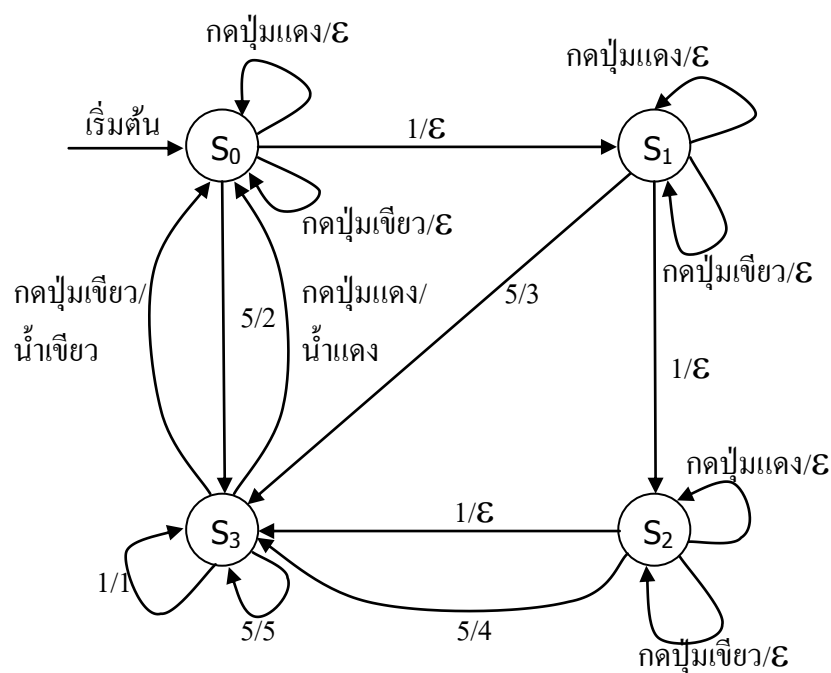

We use the label a/b on an arc from state p to state q to indicate that $\delta(p, a) = q$ and $\chi(p, a) = b$. The response of M to input 01100 is nnyny, with the sequence of states entered being $q_0 p_0 p_1 p_1 p_0 p_0$.

Theory: If M_1 is a Moore machine, then there is a Mealy machine M_2 equivalent to M_1 .

Theory: If M_1 is a Mealy machine, then there is a Moore machine M_2 equivalent to M_1 .

ตัวอย่าง การออกแบบเครื่องขายน้ำหวานอัตโนมัติ สมมติว่าเครื่องๆ นี้รับเฉพาะเหรียญ 1 บาท และ 5 บาทเท่านั้น และน้ำหวานที่ขายราคาถ้วยละ 3 บาท โดยมีน้ำหวานสองประเภท คือ น้ำเขียวและน้ำแดง เมื่อผู้ซื้อหยอดเหรียญมูลค่าครบ 3 บาทแล้ว สามารถเลือกกดปุ่มสีเขียวหรือสีแดงก็ได้เพื่อรับถ้วยน้ำเขียวหรือน้ำแดงตามลำดับ ในกรณีที่หยอดเหรียญมูลค่าเกิน 3 บาท เครื่องจะทอนเงินให้ด้วย

หรือ แสดงด้วย Transition table ได้ ดังนี้
